ARTIFICIAL INTELLIGENCE IN HEALTHCARE COMPETITION PROJECT PRESENTATION REPORT

Task: Binary Classification of Missense Variants as Pathogenic vs Benign

Competition Education Level: High School Level

Project Name:

Team Name:

Team ID:

1. TEAM CHART

The EyeP project is developed by a single-member team. The team member is responsible for all technical components, including system architecture, vision calibration algorithm design, image processing pipeline development, mobile application frontend and backend implementation, testing and quality assurance, and report writing. All technical decisions are made independently with periodic self-review against defined objectives. The project covers software engineering, image processing, and mobile application development, [illegible]

2. SUMMARY OF RELATED WORK AND CLOSEST SOLUTIONS

[illegible] adaptive display technologies relevant to the EyeP approach. The following summarises the five most pertinent works:

[1] Pamplona et al. (2010) introduced NETRA, a near-eye tool for refractive assessment using a smartphone display and clip-on lens. The study demonstrated that refractive error measurements could be obtained via an interactive pattern-alignment test, achieving accuracy within 0.5 diopters. The limitation is its reliance on external optics hardware. This work positions EyeP as a fully software-based alternative that eliminates the need for physical attachments.

[2] Huang et al. (2012) proposed a computational display technique using light field displays to synthesise images pre-corrected for a viewer's refractive error. Their system applied point-spread function (PSF) deconvolution to pre-blur images such that the viewer perceives a sharp image. Reported clinical improvements were significant for myopia and hyperopia. Key limitations include high computational cost and reliance on custom hardware. EyeP adopts a similar PSF-

compensation concept but implements it in real-time software on standard smartphone GPUs.

[3] Luo et al. (2015) explored pixel-level display compensation for presbyopia using adaptive sharpening filters applied to mobile screen content. Results showed improved legibility for text at normal reading distances. The approach was limited to static image enhancement without real-time screen overlay. EyeP extends this concept to dynamic, real-time display rendering.

[4] Kopf et al. (2016) demonstrated content-adaptive sharpening for low-resolution displays, using deep neural models to enhance edge contrast. The technique improved perceptual clarity for users with mild visual impairments. The limitation was that it required offline pre-processing. EyeP adapts edge-enhancement principles to an on-device, low-latency pipeline.

[5] Konrad et al. (2017) introduced prescription glasses-free AR displays using wavefront-coding and computational aberration correction. The system supported personalised correction profiles per user. Hardware complexity remained a barrier for mass deployment. EyeP is positioned as the scalable, hardware-free software counterpart of this concept for standard smartphone screens.

3. DATA AND METHODS

This section describes the data collection process for user vision profiling, the image processing algorithms selected for display correction, and the development methodology of the EyeP system.

3.1 Vision Calibration Data and User Profiles

EyeP does not rely on external datasets. Instead, it generates personalised vision profiles through an in-app calibration test. During calibration, the user views a series of optotype charts (Snellen-like letter and symbol sequences) rendered at varying simulated distances and blur levels. The user selects the sharpest-appearing version of each stimulus.

Responses are recorded as a vector of perceived clarity ratings across spatial frequencies (0.5 cpd to 8 cpd), enabling derivation of the user's approximate spherical refractive error in the range of -6D to +4D. This approach avoids dependency on external medical data and functions without internet connectivity. All profile data is stored locally on the device.

3.2 Data Constraints and Privacy Compliance

No external medical or clinical datasets are used. The EyeP application operates solely on user-generated calibration responses. The system does not transmit any personal data, vision profile, or usage information externally. All processing is performed on-device. This design ensures compliance with data privacy regulations (GDPR, KVKK) and eliminates risks associated with indirect data leakage. No cross-user data sharing or label lookup from external sources is performed.

3.3 Image Processing and Representation Strategy

The core image processing pipeline applies a personalised point-spread function (PSF) compensation to the smartphone display output. Based on the user's refractive error estimate, a corresponding PSF kernel is computed (Gaussian blur with sigma proportional to diopter value). The inverse filter (Wiener deconvolution) is then applied to sharpen screen content to counteract the eye's blur. Additional steps include: (i) contrast-limited adaptive histogram equalisation (CLAHE) for local contrast enhancement, (ii) unsharp masking for edge accentuation, and (iii) gamma correction to maintain perceptual brightness consistency. The pipeline is implemented using OpenCV and GPU shaders for real-time performance at 60 fps on mid-range smartphones.

3.4 Data Quality and Calibration Reliability

Calibration quality is ensured through consistency checks: if user responses deviate by more than 1.5 standard deviations across repeated trials for the same spatial frequency, those trials are flagged and repeated. A minimum of three consistent responses per frequency band is

required before finalising the vision profile. Profiles with insufficient consistency are not accepted, and the user is prompted to recalibrate under better lighting conditions. This mechanism reduces noise in the derived refractive error estimate and ensures the correction filter is grounded in reliable measurements.

3.5 Correction Scope and Risk Perspective

EyeP targets mild to moderate spherical refractive errors (myopia up to -4D, hyperopia up to +3D). Users with astigmatism, severe presbyopia, or pathological conditions are advised to continue using medical-grade corrective lenses. This scope limitation is clearly communicated to users during onboarding. False positives (over-correction) cause visual discomfort and are mitigated by conservative correction intensity defaults. False negatives (under-correction) result in insufficient clarity improvement and are addressed through user-adjustable intensity sliders.

3.6 Selected Algorithms and Rationale

Wiener deconvolution was selected as the primary correction algorithm for its mathematical optimality in minimising mean squared error between corrected and ideal images under Gaussian blur models, which closely approximates myopic and hyperopic defocus. CLAHE was chosen over global histogram equalisation for its resistance to noise amplification in low-contrast regions. Unsharp masking was selected for its computational efficiency on mobile GPUs. These three techniques work synergistically: deconvolution addresses the blur component, CLAHE improves local contrast, and unsharp masking reinforces edge clarity. No machine learning inference is required in the core pipeline, ensuring low latency and battery efficiency.

4. EXPERIMENTAL DESIGN, RESULTS, AND REVIEW

This section presents the evaluation methodology, results, and lessons learned from the EyeP prototype testing phase.

4.1 Experimental Protocol and Testing Setup

The EyeP prototype was tested with 12 volunteer participants (ages 22–58) with documented refractive errors ranging from -3.5D to +2.5D. Participants were asked to complete the in-app calibration and then read standardised text passages on the corrected display versus an uncorrected display. A within-subject crossover design was used. Each session consisted of three reading tasks per condition (uncorrected, corrected, baseline with physical glasses). Testing was conducted in a controlled indoor environment with standardised lighting (500 lux). Subjective clarity ratings (1–10 Likert scale) and objective reading speed (words per minute) were recorded.

4.2 Performance Metrics and Results

Results showed a mean subjective clarity improvement of 3.4 points (on a 10-point scale) for the corrected condition versus uncorrected ($p < 0.01$, paired t-test). Reading speed improved by an average of 18% under the corrected condition. For myopic participants (-1D to -3D), correction performance was strongest (mean clarity gain: 4.1 points). For hyperopic participants, gains were more moderate (mean: 2.6 points). Participants with mixed astigmatism showed the smallest improvement (mean: 1.2 points), consistent with the system's known limitation regarding non-spherical refractive errors. Calibration-to-correction time averaged 90 seconds per session.

4.3 Error Analysis and System Behaviour

The primary source of correction error was over-estimation of refractive power for participants who gave inconsistent calibration responses due to attentional lapses. In three cases, the derived diopter estimate exceeded the actual prescription by 0.75D, causing mild over-sharpening perceived as a halo effect. These cases were identified post-hoc through cross-referencing with participants' optical prescriptions. The system was most challenged by users with large pupils (low-light conditions) where defocus

blur is non-uniform across the pupil, violating the Gaussian PSF assumption.

4.4 Explainability and Correction Transparency

To make the correction pipeline interpretable, the application provides a visual debug mode showing the raw PSF kernel applied, the frequency response of the Wiener filter, and a side-by-side comparison of uncorrected versus corrected rendering for a sample image. This enables users to understand which spatial frequency range is being amplified and to manually adjust correction strength if the automatic result is unsatisfactory. User feedback from testing confirmed that this transparency feature increased trust in the system for 9 out of 12 participants.

4.5 Development Evolution and Lessons Learned

Initial prototypes applied global sharpening uniformly, which caused artefacts in image-heavy content such as photographs. This was resolved by implementing content-aware masking that restricts Wiener deconvolution to text and UI element regions, while leaving photographic content unmodified. A second challenge was battery drain from continuous GPU processing, addressed by implementing a selective rendering mode that only applies corrections to newly rendered screen regions. A third iteration improved calibration reliability by adding outlier rejection in the psychophysical data collection step.

5. RATIONALE FOR THE APPROACH, RESOURCE USAGE, AND ORIGINALITY

This section explains the technical justification for the chosen approach and highlights the original contributions of the EyeP system.

5.1 Why This Algorithm / Architecture?

Wiener deconvolution was chosen because it provides the theoretically optimal linear filter for reversing Gaussian blur under additive white noise, which is the dominant model for refractive defocus. Its closed-form solution enables real-time computation without iterative inference. The architecture separates calibration (run once) from rendering (continuous), minimising per-frame computational cost. This architecture generalises across device models because it operates at the GPU shader level, independent of screen technology.

5.2 Why Were Alternatives Rejected?

Two alternatives were evaluated and rejected. First, deep learning-based image super-resolution (e.g., SRCNN) was tested but exhibited unacceptable inference latency (avg. 210 ms per frame) on mid-range devices and inconsistent behaviour across content types, making it unsuitable for real-time display rendering. Second, adaptive optics simulation (wavefront-coding) required hardware modifications to the display optical stack and was therefore incompatible with standard smartphone hardware. The Wiener-based software pipeline outperformed both on the latency-accuracy trade-off.

5.3 Hyperparameter Selection and System Configuration

The Wiener filter noise-to-signal ratio parameter (K) was tuned using a grid search over K = {0.001, 0.005, 0.01, 0.05} with subjective sharpness ratings as the optimisation criterion. K = 0.005 was selected as it produced the best balance between sharpness amplification and noise suppression across participant profiles. CLAHE clip-limit was fixed at 2.0 after empirical testing showed higher values introduced graininess. Unsharp masking radius was set to 1.2 pixels based on visual quality evaluation on the reference test pattern set.

5.4 Computational Resources and Practical Deployability

Development and testing were conducted on a standard laptop (Intel Core i7, 16 GB RAM, no dedicated GPU). The deployed application runs

on Android smartphones (API level 26+) and iOS (14+). GPU shader processing averages 4.2 ms per frame at 1080p resolution, enabling stable 60 fps rendering with less than 8% additional battery consumption per hour compared to baseline display usage. Calibration runtime is under 90 seconds. Memory footprint of the correction pipeline is 14 MB. All processing is on-device with no cloud dependency.

5.5 Originality

EyeP's primary original contribution is the integration of psychophysical vision calibration with real-time GPU-based PSF compensation in a single mobile application, without requiring any external hardware or internet connectivity. The content-aware masking strategy (applying correction only to text/UI regions while preserving photographic content) is a novel design choice that prevents perceptual artefacts in mixed-content mobile interfaces. The transparent debug mode enabling user-level understanding of the correction filter is also an original accessibility design contribution. These elements collectively differentiate EyeP from prior work, which either required hardware modifications or was limited to offline image processing.
